ABSTRACT

Saudi Arabia is the largest country in the Arabian Peninsula with access to both the Persian Gulf and the Red Sea, of which it represents most of the east coast. Despite the Saudi Arabian coastline in the Red Sea being three times longer than its Gulf coast, Saudi catches from both coasts are very comparable. The catch of Saudi Arabian fisheries in the Red Sea was reconstructed from 1950 to 2010. Catch reports were searched to be used as base information for the reconstruction and for the years information was missing, they were used as anchors for estimation. The reconstruction was conducted separately for each fishery sector: artisanal, subsistence, industrial and recreational. The total catch of each sector was further divided into its taxonomic composition. The catch was low at the beginning of 1950s (7,000 t-year⁻¹). The major change in total Saudi Arabian catch occurred at the beginning of the 1980s, with the massive motorization of artisanal boats and the beginning of industrial fisheries. The peak of the total catch happened in the mid-1990s (about 50,000 t) and after which it decreased slightly to about 40,000 t at the end of 2000s. Artisanal fishery had the highest contribution to the total catch (64%), followed by industrial (23%), subsistence (10%) and recreational fisheries (3%). Although a large number of taxa were identified in the catch, few groups were dominant. The reconstructed catches were compared with the data Saudi Arabia reported to the Food and Agriculture Organization of the United Nations (FAO). The reconstructed catch was 1.5 times the Saudi catch in the FAO data from 1950 to 2010. The major differences appear following the mid-1980s, because of the industrial fishery, which then became very active and whose substantial discards remain unreported. The procedures and assumptions used here are clearly stated, because they may be useful for further research on specific aspects of the fishery, and to improve the catch time series presented herein.

INTRODUCTION

Saudi Arabia occupies 80% of the Arabian Peninsula, and has coastlines on both the Red Sea (in the southwest) and the Persian Gulf (also known as Arabian Gulf in the northeast), with the former more than three times as long as the latter. Consequently, people in the coastal areas of the lands now comprising Saudi Arabia have been fishing in both seas since ancient times. In fact, in the past, almost all coastal communities derived their entire livelihood from fishing (Neve and Al-Aiidy 1973). However, the development of fishing was uneven, with the Red Sea providing only about half of the Saudi Arabian catch despite being about three times longer.

The aquaculture sector, both freshwater and marine, has grown from 2,696 t in 1995 to 14,376 t in 2005; during that period the growth was higher for mariculture from 158 t to 11,259 t (MAW 1996, 2006).² The freshwater sector emphasizes on tilapia farming, while the mariculture is mainly for shrimp. The total aquaculture output is still growing and the amount for 2009 was about 26,000 t (Tim Huntington, pers. comm.). The rapid increase in aquaculture is in line with a government policy to supply the rapidly growing population with fish, given the stagnating yields of the capture fisheries (FAO 2003; see also below).

Saudi Arabia has the largest shelf in the Red Sea, about 70,000 km². This shelf is narrow in the north, about 40 km, but broadens in the south (Figure 1). In the

² The fishery statistics publications by the Saudi government do not have the year of publication. We have assigned them the next year of the latest data presented in the reports, e.g., data for 2005 would be published in 2006.

past, most of the landings came from the productive southern grounds, particularly those adjacent to the Farasan Banks (Barrania *et al.* 1980; Sanders and Morgan 1989). Recently, about half of the catch comes from the southern part and the rest from the central and northern part (MAW 2006). Because the Saudi Arabian coast in the Red Sea has a narrow shelf and deep water is close to shore, nutrients are rapidly lost and hence pelagic fish landings are low. The Farasan Islands (not Farasan Banks) are probably the most productive grounds in the Saudi Arabian Red Sea because of the considerable run-off. In addition, the southern part (South of Jeddah) has well developed mangroves that serve as nursery areas for many reef-associated fish (Price *et al.* 1987).

The inner shelf is characterized by shallow fringing reefs, which run for few meters to more than half a kilometer. The reefs are interrupted at the mouths of valleys or *wadi* beds, which created natural deep water harbors (Neve and Al-Aiidy 1973). The reefs are more developed in the north, while in the south the water is more turbid due to run offs from the mountainous areas and influx of nutrient rich water from the Indian Ocean through the narrow strait of Bab-al-Mandeb. There are well-developed off-shore reef systems around Al Wajh, Yanbu and Farasan Islands (Bruckner *et al.* 2011). Beyond the narrow shelf, depth increases abruptly. The coastal area is hot and dry, with air temperatures reaching more than 45°C in the hot season. There are as many as 88 settlements along the coast where fish are landed, of which some of the largest are Yanbu, Jeddah and Gizan in the northern, central and southern part of the coast, respectively. In the past, most of the supplies for fishing such as ice-making machines, engines, spare parts, gears, services, workshops were found only in the major settlements (Neve and Al-Aiidy 1973). The fishery in the Red Sea was overwhelmingly artisanal and it used mainly small boats, which started to be motorized at the end of the 1950s. By the beginning of 1990s, all the boats were motorized. The industrial fishery, experimental at first, took off at the beginning of the 1980s (Ferrer 1958; Sanders and Morgan 1989). However, due to narrow shelf area and reefs, there are no large trawlable areas to support a large number of trawlers.

The population density on the Red Sea coast of Saudi Arabia has traditionally been low, due to the dry and hot climate. The economy was based on agriculture, fishing (including pearling), nomadic herding, commerce, and since the ascent of Islam, catering to pilgrims to and from Mecca. The discovery (in 1949) and the exploitation of petroleum in Saudi Arabia profoundly modified the economy, with oil accounting for over 85% of government's revenue in the early 1970s (Neve and Al-Aiidy 1973), reducing the traditional sectors to insignificance; thus, in 1998, fisheries accounted for only 0.3% of GDP (Sakurai 1998). Easy access to air conditioners allowed major population centers to grow along the hot coast. The oil wealth also changed the demography of fisheries in that foreign fish workers, both on boats and in processing, mostly from India and Bangladesh, increased significantly starting in the mid-1980s and account for more than 60% of the fishers (Sakurai 1998). Most of the local people prefer the meat of land animals (goat, mutton, beef, chicken and camel) over seafood. On the other hand, the rather large expatriate community has a high seafood consumption, and thus Saudi Arabia imported 58,300 t, half of its seafood supply, in 1996 (Sakurai 1998) and 112,683 t, about two third of total supply, in 2003 (FAO 2003). Saudi Arabia exported a small amount of seafood, about 2,000 t in the 1990s and early 2000s, of which shrimp accounts for about 20%.

The administration of fisheries was placed under the Animal Husbandry Department of the Ministry of Agriculture and Water up to 1990. In 1991, recognizing the importance of fishery in national food security policy, the government created a Deputy Minister for Fisheries Affairs under the Ministry of Agriculture and Water, tasked to manage the fishery resources of the country. The deputy minister, in 1993, created three departments each with specific responsibilities: Marine Fisheries Department, Aquaculture Department and Marine Protection Department (Sakurai 1998; FAO 2003).

In this contribution, the Saudi Arabian fishery catches in its Red Sea exclusive economic zone (EEZ) are reconstructed from 1950 to 2010, i.e., an attempt is made to account for all catches of all fisheries (including recreational fisheries, the discards of industrial trawlers and other catches usually ignored in official fisheries statistics (see e.g., Zeller *et al.* 2011). The fisheries are reviewed and the catch standardized by the major fishery sectors in order to establish a long time series data. The fishery is divided into four sectors: artisanal, subsistence, industrial and recreational. The catches are further disaggregated into taxonomic groups. For each sector, general introduction is given, followed by a detailed description of the catch reconstruction methodology, and results and conclusions at the end.

Artisanal fishery

The artisanal fishery, sometimes referred to as 'traditional' fishery in Saudi Arabia as elsewhere, is conducted from small boats, ranging from 5 to 20 m, and simple gears with no sophisticated technologies such as winch, fish finder, electronic navigation or communication equipment (MAW 2000). Most of the boats are small 6 – 9 m, and only about 10% are bigger than 9 m. In the past, traditional boats were exclusively made of wood (locally called *sambuks* and *houris*), and used to have sails (El-Saby and Farina 1954). The fishery was not highly developed, but the economy of coastal communities depended heavily on fishing (Tefamichael and Pitcher 2006). Part of their catch was for local consumption, and part was dried or salted to be sold or bartered in exchange for other necessities (El-Saby and Farina 1954). Dried and salted fish were the only fish product to be available inland (Neve and Al-Aiidy 1973). Fishers were part time, and often would work from September to January in the agriculture sector (Gilberg 1966). Fishing was done only during the day, because it was difficult to navigate the coral reefs at night. Small boats performed day trips, but larger boats performed trips of up to 7 days (Kedidi *et al.* 1984); in some exceptional cases, even trips of up to 14 days occurred (Neve and Al-Aiidy 1973). Except for a few large boats, ice was not carried onboard, and fish were sold fresh bundled in strings (Barrania *et al.* 1980). Crew size ranged 1 to 4 per boat (Kedidi *et al.* 1984). The artisanal fishery changed with the advent of oil wealth: in 1983, fiberglass boats were introduced (Sanders and Morgan 1989) and by the mid-1990s, they accounted for about 80%, with the majority having outboard engines (Sakurai 1998). Motorization of boats started at the end of 1950s (Ferrer 1958) and was

completed by the beginning of 1990s (Sakurai 1998). The number of boats also increased in the artisanal fishery of Saudi Arabia. The dominant fishing gears are gillnet, and hook and line, which account for more than 90% of the artisanal catch, while trolling and trap are rarely used (MAW 2000). Handlining is dominant in the northern coast, targeting coral reef fishes, while gillnets are used in the southern coast, targeting pelagic fishes. Fishing licenses for the traditional fishery are issued by representatives of the Fisheries Out-Stations at the district level (MAW 2000). According to the fishery administration, traditional fishers are Saudi citizens who work on board one of their own traditional fishing boat; however, a traditional fisher can own up to 4 fishing boats (MAW 2000). Since the 1980s, most Saudi fishers are not directly involved in fishing, sometimes referred as 'investor fishers'. They own the boats, but the fishing is done by foreign workers through an arrangement where the owner gets half of the profit and the crew shares the other half. To limit effort (because catches are not increasing anymore), the issuing of new licenses has stopped in the mid-1990s (Sakurai 1998).

Subsistence fishery

The majority of the subsistence catch includes what the fishers consume and give to their families and friends to sustain their communities. These catches are not reported at all because the catch is given away before the official recording, if it exists. In the coastal areas, community members, mainly children, are also involved in catching fish for consumption by the family. For cultural and religious reasons, women are not involved in fishing in Saudi Arabia. The subsistence fishery catch can be significant. Based on interview with fishers in the Red Sea, it can amount up to half of the total catch. The catch amounts given freely have changed over time: in the past where the fishery was less commercialized, they were relatively high, but they diminished later.

Industrial fishery

The history of Saudi Arabian industrial fishery in Red Sea is tied to the history of the Saudi Fishing Company. Experimental fishing by chartered boats, mainly trawling for shrimps, started in 1952 (Ferrer 1958). The Saudi Fishing Company did not have its own boats until 1954, and it became inactive in 1961, due to engine failures, lack of maintenance and lack of profits (Gilberg 1966). The company re-established itself again in 1981, when shrimp trawling started with Thai vessels operating under contract (Sanders and Morgan 1989). Eventually, the Saudi Fishing Company grew, and owned and operated its own vessels. Currently, the company leased its operations to other companies. Its main base in the Red Sea is Gizan, in the south, close to the border with Yemen, and its main fishing grounds are located off the Farasan Islands, and near Al-Qunfotha and Al-Khoriebah. Some industrial fishing vessels operate outside the Saudi territorial waters in the neighboring countries or international waters (Sakurai 1998). Although the industrial fishery is mainly trawling (hence sometimes referred as trawl fishery), the vessels are also involved in purse seining, as well (MAW 2000). The issuance of fishing license for industrial fishing is a sole prerogative of the Minister of Agriculture and Water or the Deputy Minister for Fisheries Affairs in the same ministry (MAW 2000).

Recreational fishery

Recreational fishing was not commonly practiced in Saudi Arabia. However, once the country acquired oil wealth, and saw numerous expatriates practice the sport, recreational fishery or 'pleasure fishing', as it is called locally, took off. In the mid to late 1990s, there were 2,126 to 2,445 boats registered as 'recreational' (Sakurai 1998; MAW 2000). Most of the fishing happens on the weekend (Thursday and Friday), using handline. There are rare reports of trolling and longline fishing (MAW 2000). Recreational fishing with net is prohibited (Sakurai 1998).

METHODS

Artisanal fishery

The earliest catch estimate for Saudi Arabia's artisanal fisheries in the Red Sea was from a partial survey of the fishers from which the average catch was calculated and multiplied by the total number of fishers in order to estimate the total catch for 1953, which was 3,000 to 5,000 t (El-Saby and Farina 1954). The mid-range value 4,000 t was taken. The same amount was assumed from 1950 to 1952. After 1952, the next estimate was for 1963, from a survey which led to a total catch estimate of 5,000 t (Gilberg 1966). From 1965 to

Table 1. Sources used to adjust Saudi Arabian Red Sea catches (tonnes) reported by Sanders and Morgan (1989).

Year	Reported catch			Adjusted catch
	Sanders and Morgan (1989)	Others	Source	
1976	11,500	10,200	Peacock (1978)	-
1977	11,700	10,200	Peacock (1978)	-
1978	13,300	12,900	Barrania <i>et al.</i> (1980)	-
1979	13,100	-	-	11,328
1980	13,200	10,350	Barrania <i>et al.</i> (1980)	-
1981	13,200	-	-	11,415
1982	13,200	-	-	11,415
1983	13,200	10,742	Chakraborty (1984)	-
1984	13,200	-	-	11,415
1985	21,800	-	-	18,851
1986	22,700	-	-	19,630

1971, total catches were available for the whole of Saudi Arabia, i.e., both the Red Sea and Persian Gulf together, where it is stated that ‘about half’ of the catch came from the Red Sea (Neve and Al-Aiidy 1973). Another report gave a more precise estimate, 53%, (Barrania *et al.* 1980), which was used to calculate the Red Sea catch. From 1976 to 1986, catches from the Red Sea were estimated by halving the total Saudi Arabian reported catch (Sanders and Morgan 1989). Estimates for the Red Sea only were available for 1976 and 1977 (Peacock 1978), 1978 and 1980 (Barrania *et al.* 1980) and 1983 (Chakraborty 1984). The data from Sanders and Morgan (1989) were used for years for which there were no other estimates, after adjusting it using weighted mean for the years where there were estimates for the Red Sea only (Table 1). This resulted in that the Red Sea catch was only 86% of that reported by Sanders and Morgan (1989).

Starting 1987, data availability improved, and the following sources were used: 1987-1994 (Sakurai 1998), 1995-1998 (MAW 2000), 2004 to 2007 (MAW 2008) and 2009 (FSDP 2011). Also, the number of fishers data were available from 1991 to 2007 (MAW 2008), which was used to calculate the catch per fisher from 1991 to 2007. A linear regression was fitted to the data (Figure 2). Using this function, the catch per fisher was calculated for 1999 to 2003, which was multiplied by the number of fishers to estimate the total catch. Interpolation of the total catch was used to fill in the data gaps in 1954 to 1962, 1964, 1972 to 1975, 2008 and 2010 (Table 2).³

Part of the artisanal fishery catch is not reported at all. The major contributions to unreported catch in artisanal fisheries are fish landed outside the major landing sites where data recording occurs, if any. The second contributions to unreported catch occurs when boats land their catch at the major landing sites, but before their catch is recorded, part of the fish is sold in the non-formal market before recording. These catches are different from catch that is allocated for subsistence, which is treated separately below. It was difficult to estimate the unreported catch of artisanal fishery, as we were unable to locate pertinent studies for Saudi Arabia. We used some qualitative information that the first author collected during a field trip to the neighboring Red Sea countries of Sudan, Eritrea and Yemen (Tesfamichael *et al.* in press). The market and data recording infrastructure improved with the motorization of artisanal boats starting the beginning of 1960s facilitated by the government. This knowledge, jointly with the general pattern of the fishery, was used to estimate the unreported catch. The reconstructed time series reported Saudi artisanal catch can be divided into three phases (Figure 3): low catch level until 1963, a slight increase until 1984, and rapid increase after that, followed by decline. Thus, we assumed conservative unreported catch to be 30 % of the total catch from 1950 to 1963, 20 % from 1964 to 1984 and 10 % from

Figure 2. A linear function fitted to the catch per fisher in Saudi Arabia’s Red Sea artisanal fishery.

Figure 3. Reconstructed Saudi Arabian artisanal Red Sea fishery catches. (Note that apparent constancy of ‘unreported catch’ is a reflection of the improvement of data recording system).

³ When this report was being published Saudi Arabia published fishery statistics up to 2010. Our estimates are very similar to the official published values.

1985 to 2010. In addition, fishers from Jordan fished in Saudi waters from 1950 to 1984 (Tesfamichael *et al.* 2012). The catches were very small (maximum of 100 t) compared to the Saudi catch (minimum of 5,700 t); nevertheless they were included with the unreported catch.

Catch composition data for Saudi Arabia's artisanal fishery were available for some years, the earliest being 1980. Data points were often only available for the major target species, reflecting the over-aggregated nature of the reported data. From 1950 to 1998, where the catch composition was highly aggregated, we created a comprehensive catch composition list consisting of 20 major taxa and the category 'others' for the species not identified. To fill the species composition matrix for all the years, some aggregated taxonomic groups were disaggregated using data from other years. Indian mackerel and Spanish mackerel ('kingfish') were reported as 'Mackerel' for the 1980 and 1983 (Barrania *et al.* 1980; Chakraborty 1984). This category was split based on disaggregated ratio reported for 1985, i.e., kingfish 91% and Indian mackerel 9% (MAW 1986). The same source was used to split parrotfish and surgeonfish, with contribution 98% and 2%, respectively. Tunas were reported separately for most of the years, but not for all years. For 1985, their catch was calculated by splitting the reported 'others' using the proportion of tuna relative to 'others' for 1983. The catch ratio of tunas for 1995 (MAW 1996) was assumed to be similar to 1996 (MAW 1998; Sakurai 1998). Catch rates for cobia, wrasses, sea breams, rabbitfish, goatfish and cutlassfishes were not available for 1980 and 1983. We estimated their proportions from 'others' using ratios reported for 1985 (MAW 1986). The final result is a standardized catch composition (Table 3).

Table 3. Source for catch composition (%) of Saudi Arabian Red Sea artisanal fishery.

The most detailed (disaggregated) catch composition available was from 2004 to 2007 (MAW 2008). The catch was divided into 40 taxonomic groups and 'others' (Table 4). The 40 groups included all the 20 groups from 1950 to 1998 and 20 new ones. The 'others' from 1950 to 1998 were further divided to the 20 new groups in 2004-2007 using their average ratios. For the years catch composition was missing altogether, it was estimated by interpolating between the closest years for which catch composition was available. From 1950 to 1979, the catch composition was estimated using the earliest available ratio (1980). From 1986 to 1994, the phase of the Saudi artisanal fishery characterized by high catches (Figure 3), the only catch composition available was for 1985, and it was used for the whole period. Species composition data were also missing for the period 1999 to 2003, the mean of 1996 to 1998 and 2004 to 2007 (i.e., similar phase of the fishery; Figure 3), was used. From 2008 to 2010, the catch composition of 2007 was used. The final catch composition of the artisanal fishery consisted of many taxa but for clarity of presentation of the result only the major taxa are included and the minor taxa are lumped together in the group 'others' (Figure 4). The detailed composition is presented in the Appendix Table (A1).

Subsistence fishery

The amount of the subsistence catch was estimated based on information obtained through interviews with fishers in the Red Sea areas of Yemen, Eritrea and Sudan (Tesfamichael *et al.* in press). The amounts of fish allocated for subsistence changed over time; in the past: when fishing was mainly for subsistence, catch rates were high, and there was lack of extensive marketing, fishers reported to give about half of their catch. But later, as their catch became more valuable and their catch rates started to decrease; fishers gave less of their catch away. In order to capture the different phases of the fishery, we used the trend of the total reported catch of the artisanal fishery (Figure 3). The Saudi reconstructed reported artisanal catch can be divided into three phases: low catch level until 1963, which is the pre-motorization phase; a slight increase until 1984, and rapid increase after that, followed by decline. We assumed the subsistence fishery to be 30% of the artisanal catch until 1963. This is a conservative estimate, because fishers told us in the years before motorization gained momentum, they used to give up to 50% of their catch away. For 1964, the subsistence percentage was reduced to 20%, and for 2010 only 10%. From 1965 to 2009, the percentages were interpolated. Before these percentages were applied, some taxa not usually given away were eliminated. The taxa included the ones usually targeted for the export market, i.e., shark fished for their fin and many invertebrates such as shrimp, crab and lobster. Traditionally most of these taxa were not consumed locally and their consumption

was introduced by foreigner (mainly European) visitors to the region. Nowadays, they are consumed by the communities mainly in the affluent bigger urban centers, yet still not given freely to family and friends. The local names of most of these taxa are based on European names, rather than Arabic as is the case for most of the fish (Tesfamichael and Awadh 2012). The remaining taxa of the artisanal fishery constitute the composition of the subsistence fishery (Figure 5, Table A2). Thus, to clarify: our definition of subsistence fishery considers only the portion of the catch that is not sold by the artisanal fishers. We ignore classifications, wherein the entire artisanal fishery, especially before motorization was considered a 'subsistence fishery'.

Industrial fishery

An exploratory trawl fishing conducted for the Saudi Fishing Company in 1952 initiated industrial fishing in the Saudi Arabian waters of the Red Sea (El-Saby and Farina 1954; Ferrer 1958). The company became inactive and closed in 1961 (Gilberg 1966), but re-established itself in 1980 and carried out trial trawling until it started commercial operation in 1982 in the southern part of the Saudi Red Sea coast around Gizan (Sanders and Morgan 1989). The sporadic experimental trawling in the early 1950s, which yielded negligible catches, are not included in this reconstruction. Rather, it starts in 1982, with a first substantial catch, of which 466 t of shrimp and 703 t of fish were retained. The dataset is not continuous after 1982, but catch data were available for some years: 1987 to 1996 (Sakurai 1998), 1997 to 1998 (MAW 2000), 2004 to 2007 (MAW 2008), and 2009 (FSDP 2011) which were used as total reported catch for the respective years (Table 5). For the periods where catch was not reported 1983 to 1986, 1999 to 2003, 2008 and 2010, interpolation was used to fill in the gaps. The interpolation for the earlier period reflects the rapid expansion of the industrial fishery in Saudi Arabian Red Sea (Sanders and Morgan 1989), while the latter period depicts a somewhat stable high catch.

For the years data were available, the sources reported total (both fish and shrimp) catch or usually the commercially lucrative shrimp only. To reconstruct the catch composition, first a continuous shrimp catch was established from 1982 to 2010. Shrimp data were available for 1982 (Sanders and Morgan 1989) and 1987 to 2007 (MAW 2008). The missing data from 1983 to 1986 were interpolated between the 1982 and 1987 data and for 2008 to 2010 the ratio of shrimp to the total catch for 2007 (11%) was applied (see Table A3) for the total reconstructed shrimp data). Then, the shrimp catches were subtracted from the total reconstructed to determine the total catch of fishes, i.e., non-shrimp retained catch. This procedure was used to get the best possible species distribution as available shrimp catches went back to the early 1980s, whereas the retained fish was available only for 1997 and 1998 (MAW 2000) and 2004 to 2007 (MAW 2008). The catch compositions of 1997 and 1998 were highly aggregated in 5 major groups and more than 30% in the category 'others'. However, the data from 2004 to 2007 were more detailed with 31 groups and 'others'. The category 'others' for 1997 and 1998 was further disaggregated using the average of 2004 to 2007. From 1982 to 1996, the catch composition of 1997 was used, from 1999 to 2003, the average of 1998 and 2004 was used, and for 2008 to 2010 the composition of 2007 was used (Table 6). The shrimp catch was added to the non-shrimp catch to establish the composition of the industrial total catch of Saudi Arabia in the Red Sea (Figure 6, Table A4). Of the shrimp catch, *Penaeus semisulcatus* accounts for more than 90% (Sakurai 1998).

Unlike the artisanal fishery, where the main source of unreported catch is the catch landed without being recorded, the main source of unreported catch for the industrial fishery of Saudi Arabia is discarding. Data of retained catch were collected using logbook (MAW 2000). Fish thrown overboard (i.e., non-target species or the young of target species) usually have a low market value and are not recorded in the logbook at all. In the Saudi fishery recording system, the catches of industrial fisheries are not separated by gear, i.e., only the total is given, and usually, the same vessels use both trawling and purse seining gears (MAW 2000). Estimating the unreported catch from the total industrial catch would be misleading, because the source of discard is trawling and the proportion of trawl and purse seine catch is not constant. Using the percentage of shrimp and Indian mackerel, the main catch of trawl and purse seine, respectively, from the total catch for the years data were available for both; we found that they have inverse relationship, i.e., when the share of one increases that of the other decreases indicating the relative

share of each gear (Figure 7). Because of its high value shrimp is the main target of trawling, the main factor in discarding fish, and because a wider coverage of shrimp catch data were available; the reconstructed shrimp data were used as a base to estimate the amount of unreported catch. Estimates of retained and discarded catches were available from experimental fishing in 1952/53, where it was found that for 750 kg of retained catch, 1.5 to 2.0 t were discarded (Ferrer 1958). Taking the mid-range, discards were 2.3 times the retained catch or 70% of the total catch. However, these values cannot be used directly as the retained catch (despite the main target being shrimp) contains other species and our base of estimating unreported catch is shrimp. The earliest, which is also the highest, percentage of shrimp in the retained catch was 40% for 1982 (Sanders and Morgan 1989), and is used to calculate the amount of shrimp in the retained catch of the experimental fishing. Using these ratios, the discard was calculated to be 5.8 times the shrimp catch. This is a conservative estimate because shrimp accounting 40% of retained catch is high and for other countries in the Red Sea discard can be more than 6 times the amount of shrimp catch (Tesfamichael and Mohamud 2012).

Figure 6. Composition of the retained industrial fishery catch of Saudi Arabia in the Red Sea.

The species composition of discarded catch is different from that of the retained catch. There was no any data for the composition of discards from the Saudi Arabian Red Sea trawl fishery. However, such data were available from the Yemeni part of the Red Sea (Walczak 1977), which was used for Saudi Arabia with some modification. Jacks, lizard fish, breams, grunters, catfish and barracuda were reported as discards in Walczak (1977). They were removed from the discard list of Saudi Arabian industrial fishery, as these species were believed to have been retained (Sanders and Morgan 1989). The remaining taxonomic groups of the discard were scaled to make the total 100% (Table 7). The final catch composition is presented in Figure (8) and the actual values in Table (A5).

Recreational fishery

Very little data were available for Saudi Arabia’s recreational fishery catches. They have not traditionally been accounted for in the reported fisheries statistics, possibly because their catch is very small compared with artisanal or industrial fisheries. The only catch estimate available was 1,500 t for 1998 (MAW 2000). This tonnage was used as anchor point. We assumed, in lack of other data, that recreational catches had been ongoing since the beginning of 1970s. This is the time the oil wealth started to have effect in the fishing sector. Many Saudi citizens started to buy fiberglass boats and hired foreigners to do the fishing (Sanders and Morgan 1989; Sakurai 1998) while they would go fishing for pleasure usually in the weekend. Thus, the catch was assumed to be zero until 1969 and interpolated between 1969 and the anchor in 1998. The population size of Saudi Arabia was used as a proxy to calculate the recreational fishery catch from 1998 to 2010 using the 1998 catch as anchor.

Recreational catches were reported to consist mostly of emperors, then sea breams followed by groupers (MAW 2000). We transformed this qualitative information (using 10% steps between the ranked groups) into percent contributions, which yielded: emperors (Lethrinidae) = 40%; sea breams (Sparidae) = 30%; groupers (Serranidae) = 20% and ‘others’ = 10% (Figure 9, Table A6).

Comparing reconstructed catch with the FAO data

The reconstructed catch was compared to the catch reported in the United Nations Food and Agriculture Organization (FAO) database on behalf of Saudi Arabia (www.fao.org/fishery/statistics/software/fishstat/en). FAO uses broad statistical areas to geographically subdivide catches, and in the case of Saudi Arabia, both coasts fall in the same statistical area (‘Western Indian Ocean’). Thus, the Saudi Arabian catch reported to FAO needed to be divided into the two coasts. This was done using reports that allocated ratios to the Red Sea and the Persian Gulf (Table 8).

The earliest available Red Sea-to-Gulf ratio was for 1979 (Barrania *et al.* 1980), 1987 to 1998 (Sakurai 1998; MAW 2000) and 2000 (FAO 2003). For 2002, the Regional Commission for Fisheries (RECOFI 2009), which is active in the Gulf, reported the Gulf catch of Saudi Arabia, which in turn was used to calculate the percentage for the Red Sea. In more recent years, Saudi Arabia published annual fishery statistical reports, separate for each coast, which we relied on for 2004 to 2007 (MAW 2008). The latest year with data disaggregated between the two coasts was for 2009, and statistical data were presented separately for the artisanal and industrial sectors in the Red Sea and the artisanal sector in the Gulf (FSDP 2011). The industrial catch in the Gulf was calculated using the ratio for the two sectors in 2007, where industrial catch was 0.38% of the artisanal catch.

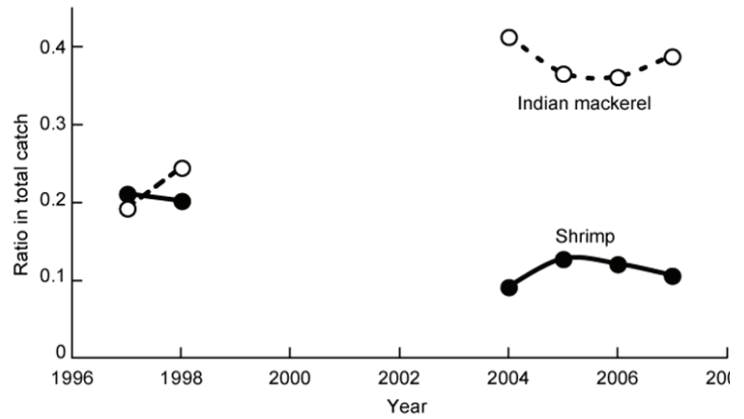

Figure 7. The contribution of shrimp and Indian mackerel to the total industrial catch of Saudi Arabia in the Red Sea for the years data were available.

Goatfish	1.0
Mantis shrimp	1.0
Others	8.2

Figure 8. Composition of the discarded industrial fishery catch of Saudi Arabia in the Red Sea.

For years where data were not available, they were estimated using different methods. For 1950 to 1960 and 1975 to 1978, the earliest available data (for 1979) were used. Using the 1979 Red Sea-Gulf ratio for 1961 to 1974 resulted in unreasonably very high Red Sea catches, thus a different approach was used for this period. The closest period with data that separates the Red Sea and Gulf catches was for 1987 to 1994. Thus, an average ratio was calculated for the total reconstructed Red Sea catch without the industrial discard to the FAO catch of Red Sea from 1987 to 1994. (Note that discarded catches are not reported to FAO at all). The result, that FAO Red Sea data were on average 92% of the reconstructed catch, was used to calculate the FAO Red Sea catch for 1961 to 1974. Then the FAO Gulf catch was obtained by subtracting the Red Sea amount from the total Saudi catch in the FAO database. The same ratio was also used for the period 1980 to 1986. Although there were ratios available for 1995 to 1996, they resulted in the FAO Red Sea catch being slightly higher than the reconstructed catch, which is unrealistic given the pattern for the other years. Thus, the reconstructed catch (without industrial discard) is assumed to be equal to the FAO Red Sea catch. For 1999, 2001, 2003, 2008 and 2010, the ratios were interpolated from the neighbouring years (Table 8).⁴

Figure 9. Catch composition of Saudi Arabia's recreational fishery in the Red Sea.

Once the FAO data for Saudi Arabia in the Red Sea were separated, they were compared with our reconstructed catch. The FAO data have more taxa (127) than the reconstructed catch, which is strange given that we used the Saudi official national and technical reports for our catch reconstruction. The large number of taxa started in 2000 when the country introduced an extensive data recording and reporting system. Most of the taxa that were included starting in 2000 have very low catch amounts and they were aggregated as 'miscellaneous' in the national reports we used. To make full use of the additional information on catch composition in the FAO data, it was used to further disaggregate the reconstructed catch composition. First the distribution of the taxa were verified using FishBase (Froese and Pauly 2012) to check if each taxon was to be included in both the Red Sea and the Gulf or only in one of these bodies of water. Then, for the taxa included in the FAO data, but not in the reconstruction, the ratios of the taxa in the FAO data were used to disaggregate the catch composition of the reconstructed data. For example, in the reconstructed catch, there was only one taxon item for groupers (Serranidae), but in the FAO data there were 18 taxon items for groupers, mainly species, but also including Serranidae. Overall, the "Serranidae" of the reconstructed Gulf catch was disaggregated into 17 groups using their ratios in the FAO data.

After the reconstructed and the corresponding FAO catch by taxa were tabulated, comparison was done at taxonomic level. The part of the reconstructed catch that is accounted in the FAO data is referred as 'reported catch' in our result. If the value of a taxon in reconstructed catch was higher than its value in the FAO data, then the difference was labeled as 'unreported catch'. If the FAO value for a taxon was higher than the reconstructed catch, the difference is over-reported catch in the EEZ of Saudi Arabia in the Red Sea. Since, the comparison of the reconstructed catch with the FAO data has modified the catch composition of the reconstructed catch, the final ratios are not exactly what are reported in the methodological tables given in the above.

RESULTS AND DISCUSSION

The Saudi fishery in its Red Sea EEZ had, for a long time, catches less than 10,000 t·year⁻¹. The fishery was dominated by traditional fishers who used small sailing boats and simple gears for decades (El-Saby and Farina 1954; Neve and Al-Aiidy 1973; Tesfamichael and Pitcher 2006). The catches were largely for subsistence and very localized markets, and the fishery lacked modern technology. The rapid change started at the beginning of 1980s, when the catch increased drastically to attain its maximum in the mid-1990s. After the mid-1990s, the total catch was declining, but remained higher than in the earlier years. The maximum catch attained was around 50,000 t in 1994. The rapid increase in the total catch starting the 1980s is due to the motorization and the introduction of fast fibreglass boats in the artisanal fisheries (Sanders and Morgan 1989; Sakurai 1998), which resulted in higher catches (Figure 10, Appendix Table A7). The artisanal and subsistence fisheries were the only ones operating in the Red Sea until the 1980s, when the industrial and recreational fisheries started, and contributed to a drastic increase of the total catch (Sanders and Morgan 1989). The catch of the artisanal fishery decreased dramatically in 1995, but this was compensated for by an increase of the industrial catch. The contribution of the recreational fishery was very low. The slight decrease from the peak is taken as a sign of resource depletion by the fisheries administration and precautionary approaches are being considered, for example new licenses are not issued (MAW 2000). Overall, artisanal fishery contributed to the highest to the total catch from 1950 to 2010 (64%), followed by industrial fishery (12%), discards (11%), subsistence catch (10%) and recreational fishery (3%).

⁴ After the completion of the report, we came to realize that data only for the gulf were available at FAO/RECOFI. Our sources gave us similar results. In addition we used the FAO data only as a way of comparison and did not have any impact in our reconstruction.

Table 8. Ratios used to calculate the Red Sea catch from Saudi Arabia's catch reported to FAO.

Year	Red Sea	Source/Remarks
1950-60	52.74	1979 values
1961	39.01	FAO Red Sea catch assumed to be 92% of reconstructed catch

The reported catch (the reconstructed catch accounted in the FAO data) had the highest contribution to the total catch (54%). The discarded catch (11%), originating from the trawl fishery, appeared only since 1982 when the Saudi industrial fishery started operating in the Red Sea. The unreported landed catch accounted for 35%. The reconstructed catch and the catch reported by FAO on behalf of Saudi Arabia assigned to the Red Sea were close to each other from the 1960s to mid-1980s. The major differences are in the 1950s and from the mid-1980s on (Figure 11, Table A8). In the 1950s, there was not any catch recording system. The fishery was traditional and there was no regulatory body, hence its catches were not properly reported. The main difference after the mid-1980s is the discarded catch of the industrial fishery, which is included in the reconstructed catch, but missing in the data supplied to FAO. As in many other sub-tropical fisheries, the Saudi Red Sea fishery catch consisted a very large number of taxonomic groups. However, only 5 taxa made up 50% of the total catch from 1950 to 2010: Spanish mackerel (17%), emperors (9%), jacks (9%), groupers (8%) and pony fish (7%). These dominant taxa are caught by artisanal fisheries. The

highest contribution of the industrial fishery were pony fishes (Family Leignathidae, which are systematically discarded) and which, with 7%, ranked fifth in the total catch (Figure 12, Table A9).

This long time series of reconstructed Saudi Arabian catches in the Red Sea, the first of its kind, is very informative, and should be useful in the assessment and management of the fisheries (Tesfamichael 2012). Unreported catches are estimated for the different sectors given explicit assumptions, on the basis of the best information available. Some of the procedures and assumptions used here will certainly require correcting when new information is available. In the meantime, this is provided in the hope that it will be found useful.

Figure 10. Reconstructed catch of Saudi Arabia in the Red Sea by sectors and its comparison to the data reported by FAO on behalf of Saudi Arabia.

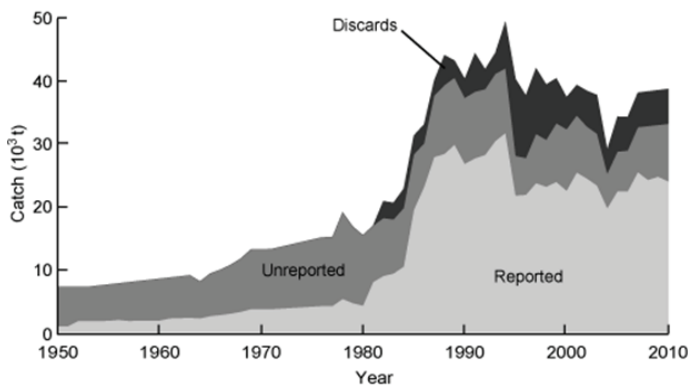

Figure 11. Reconstructed catch of Saudi Arabia in the Red Sea by components. Reported catch refers to the part of the reconstructed catch accounted in the FAO data.

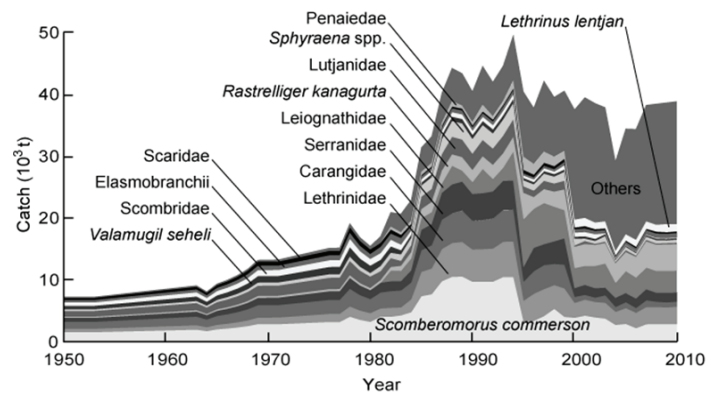

Figure 12. Composition of the total catch of Saudi Arabia's fisheries in the Red Sea.

ACKNOWLEDGMENTS

We thank Tim Huntington of Poseidon Aquatic Resource Management Ltd for his collaboration in providing us with the data of Saudi Arabian fisheries and also for his constructive comments on our first draft. Our gratitude goes to Julia Spät and Andrew Bruckner for their help with reports of Saudi Arabian fisheries and the latter for reviewing the draft. We also thank Daniel Pauly for his encouragement and copious comments on the draft. This research was supported by *Sea Around Us*, a scientific collaboration between the University of British Columbia and The Pew Charitable Trusts.
