Abstract

The Democratic People's Republic of Korea (DPRK or North Korea) is located on the northern portion of the Korean Peninsula. Unlike most coastal countries in the world, North Korea does not report its annual marine fisheries catches to the United Nations Food and Agriculture Organization (FAO) although it is a member country of FAO. We independently reconstructed North Korea's total marine catches within its EEZ for the 1950-2010 time period. The reconstructed catch estimate is the sum of an estimate of subsistence catches based on information on consumption and a re-estimated commercial fisheries catch from the FAO and the South Korean government statistics department. Total reconstructed catches were estimated to be 38.3 million t for the 1950-2010 period, increasing from 0.43 million t·year^{-1} in 1950 to a peak of 1.28 million t·year^{-1} in 1978, before declining to 0.2 million t·year^{-1} by 2010. In comparison, landings data presented by FAO amount to 24.4 million tonnes for the same period, resulting in estimated total catches being 60% larger than presented landings. Since the early 1990s, North Korea has relied heavily on international food aid. Thus, marine resources and fisheries production in North Korean waters are crucial to food security and the economy of the country.

Introduction

The Democratic People's Republic of Korea (DPRK or North Korea) is located between 38°-43°N and 124°-131°E on the northern portion of the Korean Peninsula, within Food and Agriculture Organization (FAO) statistical area 61, the Northwestern Pacific (Figure 1). The neighboring countries are the Republic of Korea (ROK or South Korea), China, Japan and Russia. The country's mainland and islands comprise a land area of around 120,000 km^2, with a total population of approximately 24 million in 2009 (www.kosis.kr). The Exclusive Economic Zone (EEZ) comprises a sea area of approximately 115,000 km^2 (www.seaaroundus.org) where both commercial and subsistence fishing activities take place.

History

After WWII, the Korean peninsula was divided geographically and politically, with a socialist regime in the north and a democracy in the south. North Korea, backed by the Soviet Union, invaded South Korea, thus igniting the Korean War from 1950-53. Kim Il Sung, the founding president of North Korea, isolated the country by creating a philosophy called 'Juche'. Although 'Juche' is originally based on the belief that "man is the master of everything and decides everything", Kim Il Sung re-directed this to 'independent stand' or 'spirit of self-reliance' and used this philosophy to justify its political decisions against outside influence. As a result, North Korea became one of the most closed socialist regimes in the world. In 1991, when the Soviet Union collapsed and eliminated oil and food exports at subsidized prices, North Korea's fisheries and agriculture production began to decline (Meditz *et al.* 2008). Furthermore, China started to decrease exports of food, fertilizer and oil. With these economic crises, several decades of resource and economic mismanagement have resulted in a heavy reliance on international assistance to feed an increasingly impoverished North Korean population[1]. For example, Ae Ran Lee (2009) examined 353 North Korean defectors to study the changes in the North Korean diet before and after the 1990s, and suggested that the amount of food distributed started to decrease after 1973, and the frequency of food distribution decreased considerably as of 1990. By the end of the 1990s, the distribution of food stopped in most areas of North Korea (Anon. 2011).

Figure 1. Map of Democratic People's Republic of Korea (DPRK or North Korea), showing the country's EEZ claim (solid line) within FAO statistical area 61 (inset).

[1] https://www.cia.gov/library/publications/the-world-factbook/geos/kn.html [accessed: August 05, 2011]

Although people have started buying food on the black market, malnutrition is still prevalent (Lee 2009). Even the military forces that have priority in food rations have not received adequate food rations and are becoming increasingly malnourished.[2]

Fisheries

North Korea's EEZ is separated into two seas: the East Sea and the western Yellow Sea (Figure 1), both of which have distinct marine geography and ecosystems. The eastern sea has a simple coastline with very few islands and a steep slope dropping to a mean depth of 1,700 meters (Kim 1994). Within this area, both the warm Kuroshio current and the cold Oyashio current intersect, creating favorable fishing conditions for both warmer water species such as Alaska pollock (*Theragra chalcogramma*), Pacific herring (*Clupea pallasii pallasii*), yellow striped flounder (*Pseudopleuronectes herzensteini*), and Ayu sweetfish (*Plecoglossus altivelis altivelis*), as well as colder water species such as Japanese pilchard (*Sardinops sagax*), Japanese anchovy (*Engraulis japonicas*), and Pacific saury (*Cololabis saira*) (Nam 2006; en.wikipedia.org/wiki/Ocean_current). In contrast, the western sea has a complex coastline with many islands (Kim 1994). The western sea gently slopes to a mean depth of 44 meters (Hong and Im 2002). This continental shelf area is an excellent fishing ground for Yellow croaker (*Larimichthys polyactis*), Hommibe croaker (*Nibea mitsukurii*), Japanese Spanish mackerel (*Scomberomorus niphonius*), Silver pomfret (*Pampus argenteus*), and righteye flounders (Family Pleuronectidae) (Kim 1994; Hong and Im 2002). The 6-7 meter tidal range provides for large intertidal areas where people collect marine species such as crabs and clams (Kim 1994; Nam 2006).

The number of marine species in the North Korean EEZ is estimated to be around 530, while the number of freshwater species is estimated to be around 120 (Kim 1994). Around 120 marine species, including 75 fish species and 20 mollusk species are commercially targeted (Hong and Im 2002). North Korea's fishing fleets are either small, unpowered wooden boats, less than 8 meters in length that operate near shore, or iron vessels, more than 4 tonnes in weight with powerful motors, which operate offshore (Hong and Im 2002). All fishing fleets are registered and their access to the sea is controlled by the government (Hong and Im 2002). In 1988, there were an estimated 30,600 fishing vessels, 64% being motorized and the remaining 36% being wooden boats (Kim 1994). The main commercial fishing gears used in North Korea are stow net in the western sea and trawl in the eastern sea (Kim 1994; Um and Heo 2010).

North Korea started a distant-water fishery in the northern Pacific ocean in 1962 and sent trawlers to Pakistan for fishing in 1984 (Hornby *et al.* In prep); however, due to a fuel crisis that began in the late 1980s, North Korea has virtually given up distant-water fishing and has focused on artisanal fisheries and aquaculture of seaweed and clams (Nam 2006; Um and Heo 2010). The amount of imported fuel decreased from 3.02 billion L (19 million barrels) in 1989 to 1.53 billion L (9.6 million barrels) by 1992 (Chang 1993).

FAO relies on data supplied by its member countries (Garibaldi 2012); thus, the quality of the data largely depends on each country's ability to collect comprehensive marine fisheries catch data. However, national statistics supplied to FAO have been found to generally underestimate total catches, as they mainly consist of commercial, large-scale or industrial fisheries landings (Zeller *et al.* 2007; Zeller and Pauly 2007). In the case of South Korea, unregulated commercial catches, discards and non-commercial catches such as subsistence and recreational catches, are unaccounted for in the official data. Thus, total marine fisheries catches taken by South Korea within its EEZ for the 1950-2010 time period were estimated to be 64% larger than reported data suggest (Shon *et al.*, in Prep.).

With limited food supplies, marine resources and fisheries productions are particularly crucial food sources for the people of North Korea. In fact, fish supplies almost 56 percent of the animal protein intake in the diet (Anon. 2000a). North Korea does not seem to formally report its fisheries landings to FAO. Thus, FAO has to rely on approximations or indirect reports. Underestimating total removals from the marine environment compromises sustainable fisheries management and may contribute to over fishing and further food insecurity. Thus, it is important to know how much is being caught each year, both past and present, and it is necessary to determine the status of North Korean fisheries in order to establish a baseline time series of historical catches.

The objective of this study is to collect all available information regarding unreported commercial and non-commercial catches, and to provide a more comprehensive estimate of North Korea's likely total marine fisheries catches from 1950-2010. This estimate of total marine fisheries catches can serve as a baseline for understanding issues such as resource depletion and food insecurity in North Korea.

Materials and Methods

Total marine fisheries catches taken by North Korean within its EEZ were reconstructed from 1950-2010 using a combination of landings data reported by FAO and the estimates of total North Korean fisheries catches assessed by the Ministry of Unification in South Korea. The FAO statistics were taken as representing only reported commercial landings, to which we added estimates of unreported commercial catches and estimates of small-scale non-commercial catches (i.e., subsistence catches). Commercial catch data from other sources deemed reliable were used in place of the FAO commercial landings data for some years.

Commercial landings

Reported landings

The commercial data used in this study were taken from the FAO landings database. Reported commercial landings data consist of fishery products that are sold in the domestic market or exported, and these are what the FAO typically represents in their landings statistics on behalf of a particular country.

These reported landings are catches of two fisheries operating within North Korean EEZ, artisanal (i.e., small-scale commercial) and industrial (i.e., large-scale commercial) fisheries. The definitions of these two fisheries in North Korea were not available, but we assumed that artisanal fishing vessels would be non-motorized wooden boats and industrial fishing vessels would be motorized boats which can operate more than one day per trip. Since the industrial fisheries use motorized boats and require fuel, their catches must have been affected more severely than the artisanal fisheries by the sudden fuel crisis which began in 1991. Thus, we assumed that the catch percentage of the industrial sector was higher than the artisanal sector for years prior to 1990 (70%), and rapidly decreased to 20% by 1996 and afterwards. We used linear interpolation to derived the annual catch percentages from 1950-2010 and applied these to individual species reported landings in order to derive the species landings by sector.

FAO statistical area 61 includes North Korea's EEZ and part of EEZs of Russia and Japan. Thus, we assumed that North Korea's distant water catches (estimated below) would be included in the miscellaneous marine fish category ('marine fishes nei') of FAO data. We subtracted the estimated catches of distant-water fisheries from the reported landings of 'marine fishes nei' and derived the catch percentages of artisanal and industrial sectors for the remaining reported 'marine fishes nei' landings. Also, we used the species composition of unreported landings (estimated below) to derive a breakdown for the remaining reported 'marine fishes nei'.

Distant-water (outside EEZ within FAO area 61)

North Korea started a distant-water fishery in the northern Pacific ocean in 1962 and sent trawlers to Pakistan for fishing in 1984 (Hornby *et al.* In prep). However, these distant-water fisheries catch data are not easily available; thus, the distant-water fisheries catches are only estimated for areas outside North Korea's EEZ, and still within FAO area 61. North Korea has had access to Russia's EEZ, within FAO area 61, since 1961 (Anon. 2000b). Although North Korea was allowed to catch between 18,000 – 200,000 t·year^{-1}, North Korean fisheries were only able to catch around 7,800 t·year^{-1} from 1995-1998 (Anon. 2000b; Um and Heo 2010). Therefore, we allocated 7,800 t·year^{-1} to the areas outside North Korea's EEZ (but within FAO area 61) from North Korea's catch for area 61 for the period from 1962-2010.

Unreported landings

North Korea does not normally release their fisheries catch data. Even in the few cases when North Korea released their data, these estimates were thought to be an exaggerated misrepresentation of their real catches. Thus, according to the FAO Yearbook of Fisheries Statistics (FAO 2005), FAO revised North Korea's 1961-1993 capture data using "the information in a report to FAO on anomalies in global capture statistics", which suggested that previous estimates of fishery production by North Korea were "seriously overestimated" (Nowara *et al.* 2005; L. Garibaldi, FAO, pers. comm.). We assumed that FAO lowered North Korea's landings data for pre-1991 years (Table 1). However, other sources that document North Korea's total fisheries catches persistently suggest values higher than the FAO's "adjusted landings" prior to 1991 (Table 1). Thus, the landings data from these other sources were treated as unreported commercial landings when their value was higher than the reported FAO FishStat data. In fact, FAO data were higher than these other sources only between 1991 and 1999. From 2000-2010, other sources had higher estimate of total North Korean marine catches. We assumed that the low landings for 1950 would be maintained to 1953 due to the Korean War. We used linear interpolation to estimate the annual total fisheries catches from 1950-2010.

In order to calculate the EEZ landing portion of the estimated total North Korean marine catches, we used the ratio of North Korean FAO landings data (area 61 to all areas) with an assumption that the FAO area 61 landings without the estimated distant-water catches were all taken within the North Korean EEZ.

Table 1. Comparison of FAO landings and alternate catch estimates (in tonnes) obtained from a variety of sources for some years.

Year	FAO landings	Alternate catch estimate	Sources
1950-1953	100,621	344,940	Nam (2006) with assumption
1957	293,956	580,000	Nam (2006)

[a] http://kosis.kr/bukhan/ [accessed: October 31, 2012]

Data concerning the species composition of commercial catches were limited. Thus, we used several sources to come up with a reasonable estimate of annual species composition (Table 2). Hong and Im (2002) presented a list of commercial species catch which was not year specific. To this, we added any missing taxa and their catches that are present in FAO data, trade data (Anon. 2005, 2006, 2007, 2008, 2009, 2010), and other sources mentioned below.

Table 2. Taxonomic composition applied to unreported commercial landings and reported MMF for North Korea. Percentage data derived through assumption-based consideration of source materials (Kim 1994; Hong and Im 2002; Nam 2006).

Taxon	Common Name	Catch (%)			
		prior to 1970	1989	1991	after 1996
Clupea pallasii pallasii	Pacific herring	0.057	0.051	0.059	0.063
Sardinops sagax	Pacific sardine	0	0.103	0.117	0.126
Scomber japonicus	Chub mackerel	0.115	0.103	0.117	0.126
Todarodes pacificus	Japanese flying squid	0.287	0.257	0.293	0.316
Theragra chalcogramma	Alaska pollock	0.219	0.197	0.113	0.061
Others		0.827	0.743	0.706	0.685

Alaska pollock (*Theragra chalcogramma*) and Japanese pilchard (*Sardinops sagax*) have been major commercially targeted species in North Korea since the early 19th century (Kim 1994; Nam 2006). According to Kim (1994), the North Korean government reported that they caught 2 million t of Alaska Pollock, which is 80% of their reported marine landings in 1988. However, reported catches of these two species prior to 1994 were not present in FAO statistics. We assumed that both species must have been caught by commercial fisheries prior to 1994. Though Nam (2006) stated that the pilchard stock was depleted during the late 1940s to early 1970s, we did not assign any catches to 1970 and assumed that it gradually increased from zero t·year^{-1} in 1970 to 20,000 t·year^{-1} (Hong and Im 2002) by 1989 when the industrial fisheries began to decline.

According to FAO statistics, sea urchins are not cultured in North Korea; thus, we assumed that all reported landings and exports of sea urchins are derived from wild capture fisheries. Various products of sea urchins (i.e., live sea urchin, fresh roe, frozen roe, and other processed roe) are mainly exported to Japan, and the exported amounts range from 239-1,893 t·year^{-1} during 1975-2002 (Sonu 1995; Hirai 1996; Sonu 2003). FAO statistics present sea urchin landings of 100 t in 1993; however, the amount of sea urchins exported to Japan in the same year was 1,380 t in wet weight (Hirai 1996). Another report suggests that North Korea's sea urchin catches were in fact higher, estimated at 2,000 t (Hong and Im 2002). This suggests that sea urchin landings were highly underestimated and under-reported.

Since 1984, FAO statistics present landings of 'miscellaneous marine crustaceans', but provide no further taxonomic detail. However, South Korea estimated that the annual crab catches were around 5,200 t, being 3,000 t from the western sea[3] and 2,200 t from the eastern sea (Hong and Im 2002). Although crab catches from the western sea were not separated at species level, crab catches from the eastern sea consisted of 400 t of hair crab (*Erimacrus isenbeckii*), 800 t of snow crab (*Chionoecetes opilio*) and 1,000 t of strong elbow crab (*Platylambrus validus*). Thus, we used these tonnages to derive individual species catch percentages (Table 2).

We used linear interpolation between anchor points to derive the annual catch percentages from 1950-2010 (Table 2) and applied these to the estimated unreported commercial landings and the reported 'marine fishes nei' landings from FAO. The percentage breakdown by sector (artisanal and industrial) applied to unreported catches was the same as used for the reported landings.

Discards

We define discards as catches that are caught by fishing boats but are thrown back into the sea because of their non-edible condition or low commercial value. Since North Korea does not usually release their fisheries landing statistics, we assumed that the FAO estimated data do not include any discards.

Kelleher (2005) assumed that discards are negligible in North Korea due to the severe food deficits, and assumed 0.5% of landings would be discards. Thus, we used the same discard rate and applied it to the annual estimated commercial landings of North Korea to estimate the annual discards for 1950-2010. As the species composition of the discards was not available, we assumed that it is miscellaneous marine fishes ('marine fishes nei').

Human population

Human population data were taken from the population division, population estimates and projections section of the United Nations[4]. Data are provided in five years increments from 1950 to 2010, and intervening years were interpolated to derive a complete time series of human population data from 1950-2010. North Korea's human population grew from 9.7 million in 1950 to 24.3 million by 2010 (Figure 2).

North Korea's coastal rural human population was required to estimate subsistence catches. To derive an estimate of the coastal rural population, we obtained urban and rural population ratio data for 1953-2008 (Kim *et al.* 2011; Table 3). In years without data, a linear interpolation between years of known data was done to estimate missing values. For years before 1953 and after 2008, we used the 1953 and 2008 values, respectively. As a subset of the rural

[3] http://www.unikorea.go.kr/CmsWeb/viewPage.req?idx=PG0000000345&boardDataId=BD0000183745&CP0000000002_BO0000000030_Action=boardView&CP0000000002_BO0000000030_ViewName=board/BoardView#none [accessed: August 30, 2011]

[4] http://esa.un.org/unpd/wpp/unpp/panel_population.htm [accessed: March 8, 2013]

population, the coastal rural population within 10 km coastal proximity were 2.48 million (31% of rural population), 2.87 million (32%) and 3.15 million (33.3%) for 1990, 2000, and 2010, respectively (Anon. 2012). Based on this increasing trend (approximately 1% increase in every decade), we assumed that there would be lower coastal rural population in 1950, i.e., 27% of rural population at that time. Linear interpolation between these anchor points was done to estimate the coastal rural population of North Korea from 1950-2010. North Korea's coastal rural population decreased from around 2.16 million in 1950 to 1.82 million in 1960, and subsequently increased to around 3.15 million by 2010 (Figure 2).

Table 3. North Korea's urban and rural human population ratios, 1953-2008 (Kim *et al.* 2011).

Years	Urban population (%)	Rural population (%)
1950-1952[a]	17.7	82.3
1953	17.7	82.3
1956	23.2	76.8
1960	40.6	59.4
1965	47.5	52.5
1970	54.2	45.8
1975	56.7	43.3
1980	56.9	43.1
1982	58.3	41.7
1985	59.0	41.0
1986	59.1	40.9
1987	59.6	40.4

2008	60.6	39.4
2009-2010	60.6	39.4

[a]1953 ratios carried back unaltered
[b]2008 ratios carried forward unaltered

Subsistence catches

Subsistence fisheries are considered to be non-commercial catches of the small-scale sector. Catch data for this sector are neither collected nor reported in the official landings statistics. While subsistence catch data were not readily available, we approximated catches for this sector conservatively using coastal rural population data in combination with general seafood consumption habits.

We assumed that people living in urban areas obtain seafood from either government supplies or markets for their daily consumption, and the seafood available through markets is commercially caught. We also assumed that the urban population is not involved in subsistence fishing and that only the rural population meets some of their animal protein demand through subsistence fishing. People living in inland rural areas would likely catch freshwater species and would not travel to the coast to catch marine species for subsistence. Thus, we assumed that only the coastal rural population would meet some of their seafood demand through marine subsistence fishing. This may be a conservative assumption for North Korea, especially in the last two decades when there has been severe food supply crisis.

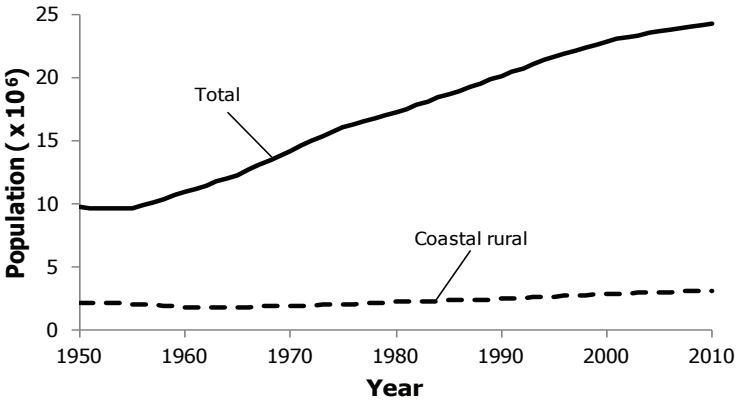

Figure 2. Total and coastal rural human population estimates for North Korea, 1950-2010.

For 1950, when the Korean War started, we assumed that North Korea and South Korea did not differ and that their coastal rural populations would have had a similar *per capita* subsistence consumption rate. Thus, we used the subsistence consumption rate of South Korea (47.6 kg·person^{-1}·year^{-1}; Shon *et al.*, this volume) and applied the same rate to North Korea.

In the 1960s, North Korea modernized their fishing vessels (Chang 1993). Thus, we assumed that the introduction of motorized vessels increased commercial catches and therefore we reduced the subsistence consumption rate by half for 1970 (23.8 kg·person^{-1}·year^{-1}).

Since the 1990s, substantial food distribution problems have caused serious food shortages in key organizations such as the military who have had to source their own food (Ishimaru 2011). More recently, military personnel stationed near the coast not only occupy all accessible beaches, but also seem to control available marine resources (Dr. S. Um, Korea Maritime Institute, pers. comm.). In fact, the "military-first" policy in North Korea allowed the military to monopolize fisheries production and isolated the benefits from most other North Koreans since 1998 (Park and Hong 2012). We assumed that these circumstances must have affected subsistence fishing opportunities in the coastal rural areas.

Since actual *per capita* seafood consumption data were not easily available, we used *per capita* seafood consumption supply data which are calculated by using commercial landings, imports, and exports data of fish, crustaceans and mollusks for 1991-2009 which range from 43.2 – 8.8 kg·person^{-1}·year^{-1} (Table 4; NOAA 1997, 1998, 2000, 2001, 2003, 2005, 2007, 2009, 2010, 2012). We used these supply rates to derive assumed marine subsistence rates by taking 35% in 1991, 30% in 1998, and 10% in 2009, with intervening years interpolated (Table 4). A linear interpolation between the 1991, 1998, and 2009 subsistence percentages was done, and applied to the supply rate to estimate the subsistence rate. Then, a linear interpolation between the 1950, 1970, and 1991 subsistence rate was done to obtain the annual subsistence rate for 1950-2009. The 2009 value was carried to 2010 to derive a complete time series of subsistence catch rates for coastal rural areas of North Korea. The total annual subsistence catch amounts were then estimated by multiplying the *per capita* subsistence catch rates by the population of coastal rural areas. As the species composition of the subsistence catches was not available, and North Korea would likely not have access to boats for subsistence fishing, we assumed that North Koreans would catch the same species that South Koreans catch or collect on the beach. We used the species composition of South Korean recreational mud flat collecting for subsistence catches of North Korea (Shon *et al.*, this volume).

Results

Commercial landings

Reported landings

The total reported commercial landings for North Korea within FAO statistical area 61 for the period 1950-2010 were 24.4 million tonnes, of which 24 million tonnes were deemed to come from inside the North Korean EEZ and 0.4 million tonnes were assumed to come from outside the EEZ but within FAO area 61 (Figure 3). In 1950, marine commercial landings from the North Korean EEZ were estimated to be 94,000 t, then peaked at about 990,000 t in 1982 and decreased very rapidly to around 329,000 t·year^{-1} by 1992. It declined further to approximately 190,000 t by 2002 (Figure 4a). Commercial landings were dominated by Japanese flying squids (*Todarodes pacificus*; 26%), Alaska pollock (*Theragra chalcogramma;* 22%), Chub mackerel (*Scomber japonicas;* 10%), Pacific herring (*Clupea pallasii pallasii;* 5%), and Pacific sardine (*Sardinops sagax;* 5%).

Table 4. Data sources for fish and shellfish consumption of the total population and estimated subsistence catch rate for coastal rural population. N/D: no data; '-' indicates interpolation.

Year	Consumption rate (kg/person/year)[a]	Source	Assumed subsistence proportion (%)	Subsistence rate (kg·person^{-1}·year^{-1})
1950	52.93	Shon *et al*. (in prep.)	90	47.36

[a] Average consumption rate is used when there are two or more sources.
[b] Assigned 50% of 1950 subsistence rate.

Unreported commercial catches

The total unreported catches within the North Korean EEZ for the period 1950-2010 were estimated to be 11.5 million tonnes, of which 3.6 million tonnes were assumed to be artisanal and 7.8 million tonnes were deemed to be industrial (Figure 4a). From 1950 to 1976, the unreported catches increased from around 230,000 to 553,000 t·year^{-1}. By 1987 unreported catches fluctuated between 0 to 34,000 t·year^{-1}. The domestic unreported landings were dominated by Japanese flying squids (*Todarodes pacificus;* 28%), Alaska pollock (*Theragra chalcogramma;* 21%), Chub mackerel (*Scomber japonicas;* 11%), and Pacific herring (*Clupea pallasii pallasii;* 6%).

Discards

The total discards of commercial fisheries within the North Korean EEZ for the period 1950-2010 were estimated to be 177,000 t (Figure 4a). The annual discards gradually increased from around 1,600 t·year^{-1} in 1950 to around 6,100 t·year^{-1} by 1978 and decreased to around 1,000 t·year^{-1} by 2010.

Subsistence catches

The total estimated subsistence catch of North Korea for the entire study period was approximately 2.6 million tonnes (Figure 4a). In 1950, marine subsistence catches were estimated to be around 103,000 t·year^{-1} and gradually decreased to approximately 4,600 t·year^{-1} by 2010 (Figure 4a). These unreported catches were likely dominated by miscellaneous marine crustaceans (25%), octopus (10%), and species of Osteridae (10%), Portunidae (10%), and Holothuriidae (10%).

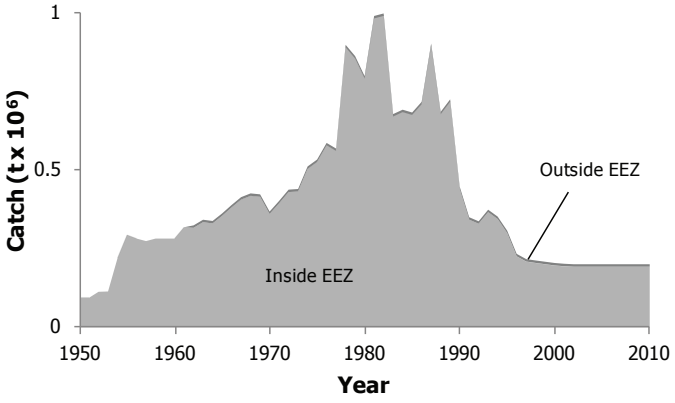

Figure 3. FAO landings data of North Korea within FAO statistical area 61 assigned to Korean EEZ and the remaining area 61. Source: FAO FishStat and (Anon. 2000b); Um and Heo (2010).

Total reconstructed catch

Total reconstructed marine catches by North Korea within its EEZ were estimated to be around 38.5 million tonnes over the 1950-2010 time period (Figure 4a). In 1950, the total reconstructed catches within North Korea's EEZ equivalent waters were 0.43 million t and gradually increased to just over 1.28 million t·year^{-1} by 1978. Catches fluctuated in the late 1970s and the early 1980s and decreased to 0.85 million t·year^{-1} by 1989. After this, there was a rapid decrease in catches to 0.2 million t·year^{-1} by the late 1990s. Thereafter, total marine catches within the EEZ have not recovered to previous catch levels and have remained around 0.2 million t·year^{-1} (Figure 4a).

Total reconstructed catches were dominated by 5 major taxa: Japanese flying squids (*Todarodes pacificus;* 22%), Alaska Pollock (*Theragra chalcogramma;* 22%), Chub mackerel (*Scomber japonicas;* 10%), Pacific herring (*Clupea pallasii pallasiii;* 5%), and Pacific sardine (*Sardinops sagax;* 4%), while an additional 42 taxa contributed 42% (Figure 4b).

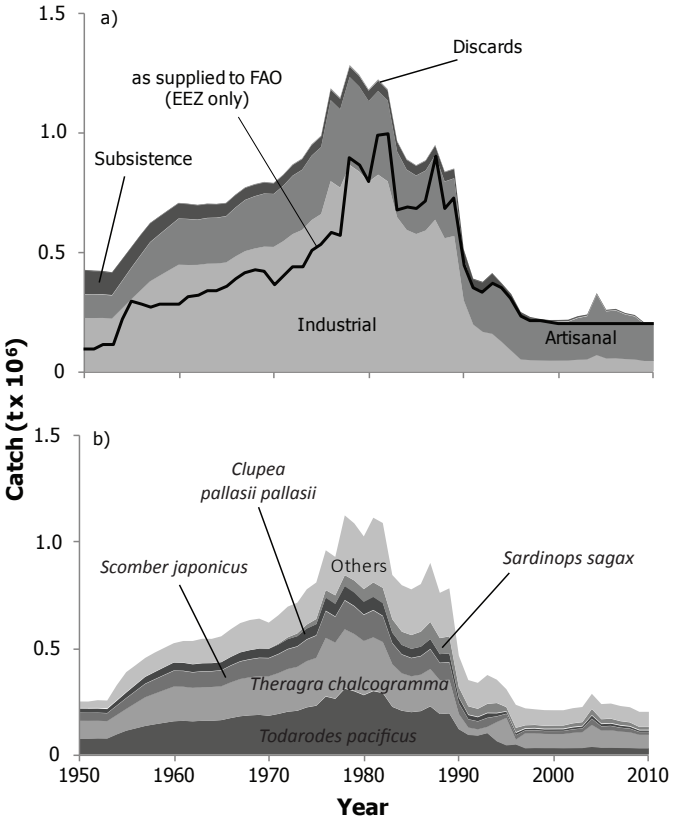

Figure 4. Total reconstructed catch for North Korea, 1950-2010, a) by sector compared to landings supplied to FAO (dotted line); and b) by major taxa with 'Others' consisting of 42 additional taxa.

Discussion

The total reconstructed marine catch for North Korea within its EEZ for the period 1950-2010 was approximately 38.3 million tonnes. In comparison, the FAO estimate for North Korea's marine commercial landings was approximately 24.4 million tonnes, resulting in reconstructed catches being nearly 60% larger than those presented by the FAO (Figure 4a). This discrepancy is largely due to the likely under-estimation of commercial landings prior to 1990. North Korea was actively supported by the former USSR until the late 1980s and therefore had substantial infrastructure (i.e., boats) and cheap oil to catch seafood. Some of the above difference is due to subsistence catches and discards being not accounted for in data reported by FAO.

Commercial catches declined rapidly during the late 1980s and early 1990s. The rapid decline was due to the shortage of subsidized fuel with the collapse of the former USSR. North Korea was suddenly left to search for other external economic support to save their economy and maintain their 'Juche' philosophy (Rhee 1991). For this reason, we assumed that catches after 1990 were mainly from inshore areas, accessible by less fuel intensive means.

Subsistence catches in North Korea showed a steady decline due to the gradual migration of the coastal rural population to urban areas and the increasing dominance and polarization of access to these resources by the military.

Unfortunately, there were no readily available catch data for other components of unreported fishing such as recreational fishing and unregulated fishing activities such as discarding. However, we assumed that no recreational marine fishing estimates exist in North Korea. Additionally, due to the food deficiency in North Korea, we assumed that discarding was also low, although some of the larger commercial vessel with export focus may engage in discarding.

Our study attempted to account more comprehensively for the total marine fisheries removals than the landings data currently presented and available for North Korea's marine fisheries, by adding estimates of non-commercial subsistence to the re-estimated commercial landings over the period 1950-2010. For developing countries, depletion of marine resources can further perpetuate economic hardships and issues of food insecurity (Kent 1997). We hope that the results of this study can help improving a historic baseline for North Korean fisheries' catch statistics.
